Research Article

Life history traits of ribbonfish *Trichiurus lepturus* (Linnaeus, 1758) in the Persian Gulf and Oman Sea

Taghavimotlagh S.A.[1]; Ghodrati Shojaei M.[2*]; Vahabnezhad A.[1]

Abstract

Ribbonfish, *Trichiurus lepturus* (Linnaeus, 1758), is an important component of subsistence fisheries throughout its tropical and subtropical distribution. The catch rate of ribbonfish has increased seven-fold in a decade in the Persian Gulf and Oman Sea. We collected monthly biological samples from *T. lepturus*, to estimate growth and mortality parameters, and identify species reproductive pattern. The annual instantaneous rate of fishing mortality (0.63 year^{-1}) was higher than the target (F_{opt}=0.26 year^{-1}) and limit (F_{lim}=0.35 year^{-1}) reference points, indicating that the ribbonfish stock is overexploited. The gonado-somatic index and monthly gonadal maturity stages of harvested fishes indicated that *T. lepturus* presents continuous reproductive activity throughout the year, peaking in the four months from February to May. The size at first maturity was estimated at 70.9 cm total length for females. The overall sex ratio differed significantly from the expected 0.5 with a larger proportion of females ($\chi2$=203.10; *p*<0.001). The current study provide important information that can facilitate management, conservation, and sustainable fishing of *T. lepturus* in the Persain Gulf.

Introduction

Many fish species in the Persian Gulf have been overfished over the past two decades, due to the increased fishing effort that exceeds the optimal level for most pelagic and demersal species (Shojaei *et al*., 2007; Taghavimotlagh and Shojaei, 2009; Grandcourt, 2012). In recent years fishermen on the northern coast of the Persian Gulf and Oman Sea repeatedly complain that the catch of fishes has declined, and thus the interest has been shifted toward the less harvested and non-exploited species (Taghavimotlagh *et al*., 2008; Hakimelahi *et al.,* 2010). Ribbonfish (*Trichiurus lepturus*) is one of the species that has been proposed as an interesting complement since early 2000s.

The ribbonfish is a bentho-pelagic species found worldwide in tropical and subtropical regions, mainly between 45° S and 60° N. (Randall, 1995). It occurs from shallow inshore waters to up to 300 m depth while aggregating in dense schools. The species switch between estuarine and marine ecosystems, according to its life cycle stage and food demand (Kwok and Ni, 1999; Elliott *et al*., 2007; Ghosh *et al*., 2009). *T. lepturus* feeds on a variety of pelagic and demersal fishes, and crustaceans, while may exhibit cannibalism toward small juvanials (Martins *et al*., 2005). Ribbonfish is a significant fish resource of the Iranian Exclusive Economic Zone (EEZ), contributing to about 5% and 13% of the biomass of the Persian Gulf and Oman Sea coasts

(Taghavimotlagh and Shojaei, 2018). The fish is not consumed by local populations and not marketed in Iran. However, it is commercially important due to its high demand for export to China and other Asian countries. The average catch has increased from 10235 tones in 1997 to 55890 tons in 2019 (Fig. 1). Surprisingly, the catch rate of ribbonfish increased seven-fold in a decade (2010 – 2019) and now ranked third among the exploited marine fishery resources of Iran. Along the coast of the Persian Gulf, it is caught by the traditional fishing sector using hand-line and drift gillnet and by the commercial sector using midwater trawling. Currently, the boats are equipped with low power light-emitting diode panels (LEDs) that are designed to increase fish attraction to the baits. Currently, the strong fishing effort, has raised concerns of possible recruitment failure on Northern coast of the Persian Gulf and Oman Sea. Developing conservation efforts require information on the past and current status of the stock and the patterns that shape the species' biological cycles. On account of the current status of ribbonfish populations, conservation measures are required, and knowledge on the species' growth and mortality rates as well as life history traits is a prerequisite for designing effective management strategies. Among the life history traits, reproduction represents significant aspects that the preservation of viable populations depending on its success (Jakobsen *et al*., 2016). Different aspects of growth and

reproductive features such as infinity length, size at first maturity, sex ratio, type of spawning, and annual reproductive cycle are essential to assess the spawning stock and used to develop the standard guidelines (Armsworth, 2001; Taghavimotlagh *et al*., 2010; Taghavimotlagh *et al*., 2012). Several studies on the growth and reproductive biology of *T. lepturus* have been previously undertaken in some regions of the northern hemisphere, including Indian Ocean (Thiagarajan *et al*., 1992), the China seas (Kwok and Ni, 1999), the SW Atlantic (Martins and Haimovici,

2000), the Arabian Sea (Al-Nahdi *et al*., 2009) and the Persian Gulf (Raeisi *et al*., 2012; Taghavimotlagh and Shojaei, 2018). To our knowledge, no study has previously examined the life history traits of ribbonfish in the Northern coasts of the Persian Gulf and Oman Sea. To help fill information gaps, we collected biological samples from *T. lepturus* harvested in the Persian Gulf and Oman Sea to estimate their growth and mortality parameters and life-history traits including sex ratio, size at first maturation (L_{M50}), reproductive seasonality, and growth.

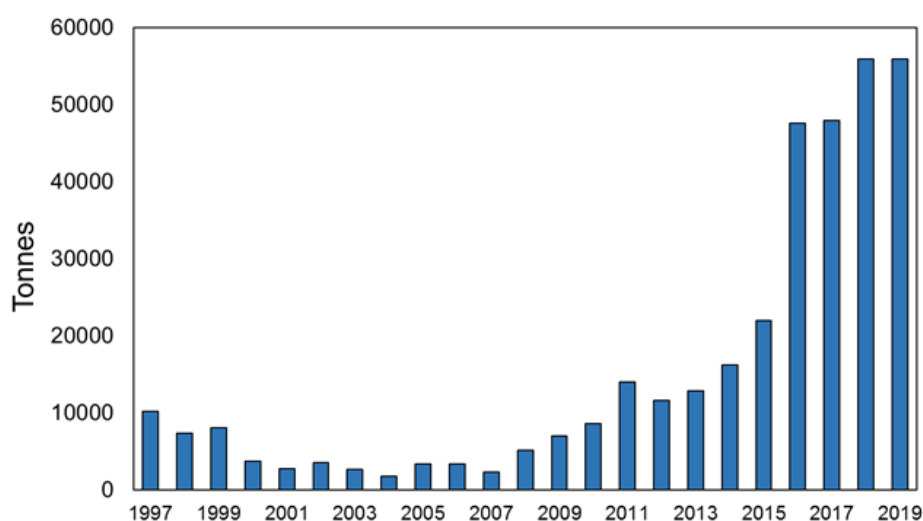

Figure 1: Trends of landings of *T. lepturus* caught in waters of Iran (Persian Gulf and Oman Sea) from 1997-2016.

Materials and methods

Sampling and measurements

T. lepturus were collected randomly from coastal waters off the Persian Gulf and Oman Sea, Iran, from March 2016 to February 2017 (Fig. 2). Fish were sampled using bottom trawls (stretched cod-end mesh size of 22 - 24 mm), gillnet, and hand line fishing

gear. During sampling events, the total length (L_T, cm) and body mass (M_B, g), were recorded for the individuals to the nearest 0.1 cm and nearest 0.1 g, respectively. In total, 3321 individuals were collected randomly from a large pool of individuals to estimate the size distribution, growth parameters, and mortality rates. Additionally, a sub-

sample of 30 to 35 individuals were monthly sampled and transported to the laboratory in ice for further analysis. All gonads (M_G) were weighted to the nearest 0.01 g with an AND scale (GF 3000; www.aandd.jp).

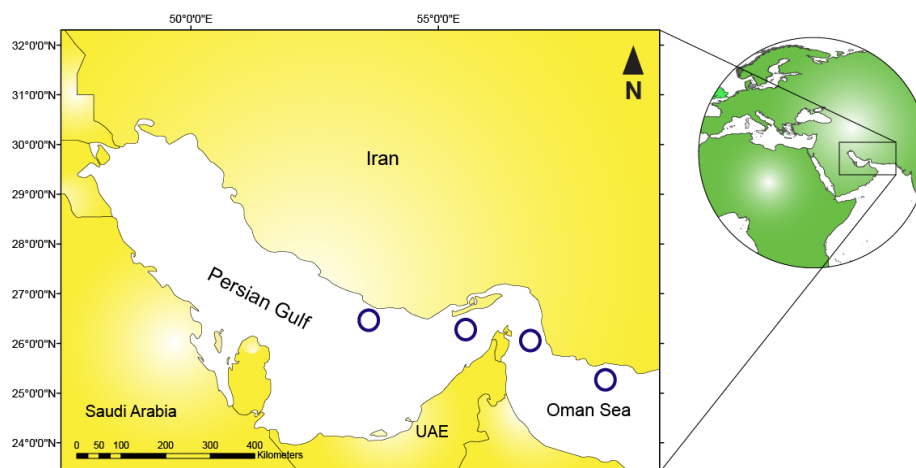

Figure 2: Sampling locations (shaded line) for *T. lepturus* in the Persian Gulf and Oman Sea, March 2016–February 2017.

Length-weight relationship

The relationship between length and body mass was calculated using: $M_B = aL_T^b$, where *a* is a scaling constant and *b* is the allometric growth parameter (Hayes *et al*., 1995). The parameters *a* and *b* were estimated by the least-squares linear regression analysis based on natural logarithms: $\ln(M_B) = \ln(a) + \ln(L_T)$ Significant difference of *b* values from the isometric threshold, *i.e.,* 3, was tested by the t-test (Pauly, 1983). The difference in L_T - M_B relationship between sexes was examined by the maximum likelihood ratio test (Kimura, 1980).

Growth and mortality

The von Bertalanffy growth function (VBGF) was used to evaluate the infinitive length (L_∞) and growth coefficient (K) of the *T. lepturus* (Pauly, 1983). The VBGF is defined as:

$$L_t = L_\infty (1 - e^{K(t - t_0)})$$

Where L_∞ is the asymptotic length, *i.e.,* the mean length that the fish of a given stock would reach if they were able to grow indefinitely; K is the growth coefficient, and t_0 is the time at which the length is equal to zero. The value of t_0 calculated using Pauly's empirical equation (Pauly, 1980):

$$Log\ (-t0) = -0.3922 - 0.275\ log\ L_\infty - 1.0381\ log\ K$$

The growth performance index (φ') was obtained using the following equation (Pauly and Munro, 1984):

$$\varphi' = logK + 2\ log\ L_\infty$$

The total mortality (Z) is the sum of the natural mortality (M), and fishing

mortality (F) was calculated using the length converted catch curve method (Pauly, 1983). Additionally, Pauly's empirical equation (Pauly, 1980) is applied to estimate the natural mortality (M) index:

$Log10 (M) = –0.0066 – 0.276 \, log10(L\infty) + 0.6543 \, log10 (K) + 0.4634 \, log10 (T)$

Where T is the annual mean of sea surface temperature (*i.e.,* 26.5°C in the Persian Gulf). Following the calculation of Z and M, fishing mortality (F) and exploitation rate (E), estimated using the functions; $F = Z – M$ and $E = F/Z$. In line with the exploitation rate, the stock status was also assessed by comparing the fishing mortality rate with the target (F_{opt}) and limit (F_{lim}) biological reference points defined

as F_{opt}=0.5 M and F_{lim}=2/3 M (Mace, 1994). The TropFishR package available in R software was used to estimate the growth and mortality rates from length-frequency data (R-Team, 2017).

Spawning pattern and length at maturity

The gonads of each fish were evaluated macroscopically for sex and stage of reproductive development based on the characteristics described by (Kwok and Ni, 1999). Six commonly identified stages were utilized as a threshold to discriminate fishes showing different gonadal stages (Table 1).

Table 1: Macroscopic criteria for assessing stages of reproductive development in female *Trichiurus lepturus,* adapted from Kwok and Ni, (Kwok and Ni, 1999).

	Reproductive stage	Macroscopic characteristic
I	Immature	Ovaries glassy, narrow and short, eggs invisible.
II	Developing	Ovary opaque, eggs distinguishable. Ovary about 50% length of ventral cavity
III	Spawning capable	Ovary yellow to orange, opaque oocytes visible through epithelium. Ovary about 60-70% length of ventral cavity
IV	Actively Spawning	Ovary well rounded, filled, hydrated eggs large and visible through epithelium, can easily be counted. Eggs transparent, can be released when pressed. Ovary about 80% length of ventral cavity. well rounded.
V	Regressing	Ovary translucid with garnet color
VI	Regenerating	Ovary shrunk and flaccid

All ovaries at stages 4 or higher were considered mature. The gonado-somatic index (GSI), was calculated by the equation *GSI(%)=(MG/MB)*100*. The sex ratio was taken across all samples for which sex could be determined and tested using χ2-test to know if the sex ratio differed significantly from a 1:1. Differences

between the mean size of females and males were tested with a two-sample independent t-test. Size at sexual maturity (L_{M50}) is defined as the size at which 50% of the fish has reached maturity and is ready to spawn (King, 2013). The proportion ($P_i=M_i/J_i$), of mature individuals by size class *(i)* was calculated in 1 cm intervals, where

(M_i)= number of mature specimens in size class i; J_i= total number of individuals examined from the same size class i (immatures and matures). To estimate size at first sexual maturity (L_{M50}), the data were fitted to a logistical function. We used the logistic curve equation (King, 2013): $P=1/1+e^{-r(L_T-LM_{50})}$, where P=proportion of mature individuals; L_T=total length corresponding to the proportion (P); r=slope of curve; L_{M50}=total length at 50% mature. All specimens assigned to III or higher stages of maturity were judged mature. All statistical analyses were conducted using Microsoft Excel 2013 and R 3.4.3 (R-Team, 2017). The raw data on growth and life history traits of *T. lepturus* is available at PANGAEA, https://doi.pangaea.de/10.1594/PANGAEA.917549.

Results

Length-weight relationship
All of the samples were phenotypically identified to species level immediately in the field following Fischer and Bianchi (1984). Females ranging in size from 50.5 to 114.5 cm L_T with a body mass of 129.3 - 937.1 g, whereas males were in the range of 53.5 - 86 cm L_T, with body mass between 114.6 and 592.5 g. Females were on average (81.55±8.95 cm L_T) larger than males (69.03±8.55 cm L_T) and this difference was statistically significant (t=1.96, $p<0.01$). From these data, mass–length relationships were generated and described by: $M_B=0.0001\ L_T^{3.47}$ (R^2=0.91; N=262, $p<0.001$) for females (Fig. 3a) and $M_B=0.0004\ L_T^{3.15}$ (R^2=0.87; N=43, $p<0.001$) for males (Fig. 3b). The differences of slopes of the length–mass regressions for males and females were significantly different (ANOVA, $p<0.01$).

Growth and mortality
The results of the response surface analysis provided the best fit of growth model *i.e.,* L_∞=121.5 cm and K=0.29. These parameters were later used in all the calculations. The values of t_0 and φ' were estimated as –0.32 year, and 3.63 respectively. The natural mortality (M) estimated by Pauly's method presented a rate of 0.53 yr^{-1}. The annual rate of total mortality (Z) derived from catch curve analysis was 1.16 year^{-1}. Using the value of Z and M, fishing mortality and exploitation rate (E) were calculated as 0.63 year^{-1} and 0.54 respectively. Biological reference points, *i.e.,* F_{opt} and F_{lim} were estimated as 0.5 year^{-1} and 0.37 year^{-1}, respectively.

Spawning period and length at maturity (L_{M50})
Sex, gonad mass, and reproductive state were evaluated from a sub-sample of 380 *T. lepturus*. Females outnumbered males throughout the year with the sex ratio of 321:59, which was significantly different from 1:1 (X^2, $p<0.01$). Males were absent from August to October and, 74% of males have recorded from February to June, which correspond to the reproductive period of *T. lepturus*.
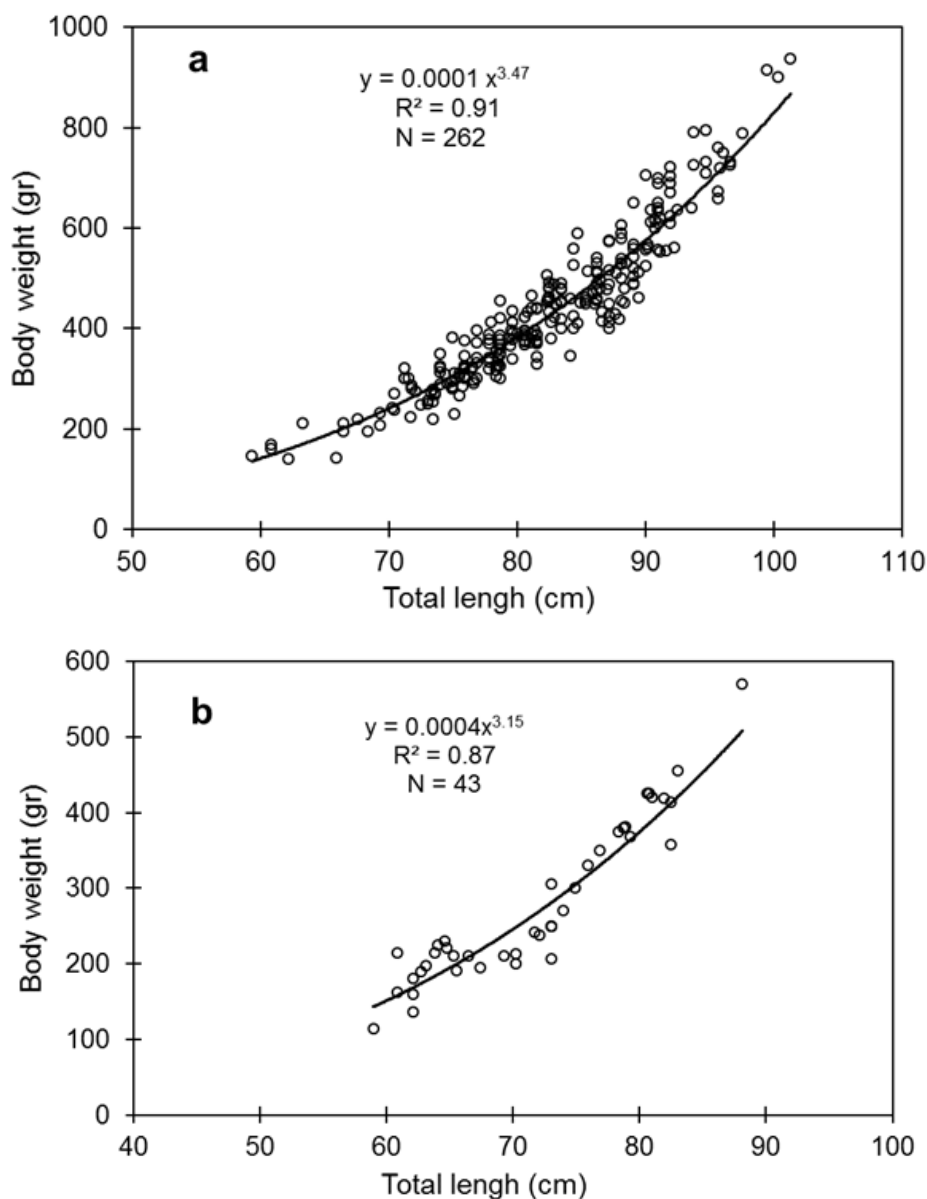

Figure 3: Relationships between total length and body weight of *T. lepturus* for (a) female and (b) male in the coastal waters of Persian Gulf and Oman Sea.

The mean GSI of females increased from 1.72 in February to a peak of 4.98 in March, decreased thereafter to the lowest value at 0.76 in September, and then gradually increased (Fig. 4). The macroscopic appearance of ovary maturity indicated that most of the immature ovaries were present from July to October, with mature ovaries appearing throughout the sampling year (Fig. 5). The smallest mature female was 66.2 cm LT. The size at first maturity of the ribbonfish females was attained at 70.9 cm LT (Fig. 6).

Discussion

The length-mass relationship showed that *T. lepturus* exhibited positive allometric growth. It agrees well with the results of studies reported from the Arabian Sea and the Indian Ocean (Reuben *et al*., 1997; Al-Nahdi *et al*., 2009; Ghosh *et al*., 2014). The small variations could be related to different biological factors such as food quality, habitat, spawning season, and a length range of sampled specimens (Balon, 1985). The ribbonfish exhibit asymptotic growth ranging from 106.82 cm L_T (Ruben *et al*, 1997) to 152.4 cm L_T (Liang and Pauly, 2017), with different growth rates ranging from 0.13 yr^{-1} (Avinash *et al*., 2014) and 0.72 yr^{-1} (Abdussamad *et al*., 2006). Growth parameters are essential parameters to estimate the stock size, recruitment, and mortality of the fish population (King, 2013). The growth parameters varied within the stocks that might experience different environmental conditions. Food availability and water temperature might influence the growth of fish and further affect the population's mean size (Yoneda and Wright, 2005). The growth parameters obtained for the present study revealed a lower L_∞ value compared to the values calculated in the Indian Ocean. . The field observations indicate that the fish mean length is generally small in the Persian Gulf compared to the adjacent region, mostly because of its harsh environmental conditions (Sheppard *et al*., 2010). In the current study, the growth rate (K) was calculated as 0.29

per year that is nearly comparable with the research done by Ghosh *et al*. (2009), but lower than that estimate (0.72) by Abdussamad *et al*. (2006). The value of performance index (3.63) in the present study was comparable with many previously published reports by similar studies in FAO 51 region (Ghosh *et al*., 2009; Avinash *et al*., 2014; Taghavimotlagh and Shojaei, 2018). In the Indian Ocean, values of φ' range from 3.35 to 4.1 (Abdussamad *et al*., 2006; Avinash *et al*., 2014). One possible explanation for such differences may be related to the fact that ribbonfish undergoes different stanzas of growth rates (Liang and Pauly, 2017). In the current study, the total mortality (Z), natural mortality (M) and fishing mortality (F) were estimated as 1.16 and 0.53 and 0.63 per year, respectively. The estimate of Z is similar to the values reported by (Taghavimotlagh and Shojaei, 2018) from the Strait of Hormuz. However, it is principally lower than those reported from India (Abdussamad *et al*., 2006). The values of exploitation rate (E), target and limit reference points confirm that the ribbonfish stock is under high fishing pressure. Higher demand for ribbonfish in recent years, together with operating improved mid-water trawl nets that catches>70% of ribbonfish, has resulted in higher catches that may lead to overexploitation. Ribbonfish trawlers conduct fishing voyages for 7-15 days beyond the EEZ (Shojaei and Taghavimotlagh, 2011). Along with commercial vessels, traditional fishing

sectors are targeting ribbonfish using boats equipped with LEDs. Available information indicates that traditional fishermen may contribute as much as 50% of the country's total ribbonfish catch.

In the current study, we found substantial differences in size between females and males with 18 cm difference in their maximum size. These differences are attributed to natural sexual dimorphism, when a large body size confers an adaptive advantage for females, possibly because large females are more fecund and lay larger eggs than small females, increasing reproductive success (Wootton, 1992; Filous *et al.*, 2019). The sex ratio of the ribbonfish population skewed towards females, which is also observed in South China coasts and Mexico (Kwok and Ni, 1999; De la Cruz-Torres *et al.*, 2014). Several factors may influence the sexes differently, including growth, mortality, and behavior (King, 2013). The observed minimum size of sexual maturation was 60.1 cm L_T for females based on the macroscopic analysis of the gonads. The size at maturity varied considerably within the specimens that might experience different environmental conditions (Froese and Binohlan, 2000). The estimated size at first maturity for females was 70.9 cm LT based on all sampled from the year-round sampling. Various authors reported different size at first maturity f or *T. lepturus* in different water bodies of the world. Martins and Haimovici (2000) estimated the size at maturity of

T. lepturus to be 69.3 cm L_T in southern Brazil. From work done on a fish community on the northwest coast of India, Khan (2006) noted that the size at maturity is 75 cm L_T. Al-Nahdi *et al.* (2009) showed that maturity is reached at 79 L_T in the Arabian Sea. The small range of sizes at maturity attribute d to variability in growth rates and lifespan and suggests the adaptability of the ribbonfish to different environments (Martins and Haimovici, 2000). Food availability, stock density, and water temperature might influence the growth of fish and further affect their gonadal development and size at first maturity (Yoneda and Wright, 2005). Generally, higher estimates of size at Maturity for *T. lepturus* correspond to the regions where marked temprature cycles and lower annual mean temperature occur. The Persian Gulf is categorized as subtropical and usually does not undergo marked temperature cycles (Sheppard *et al.*, 2010). Additionally, field observations indicate that the fish population size is generally small in the Persian Gulf compared to the adjacent region, mostly because of its harsh environmental conditions. As the L_{M50} is useful for overfished species management, this information can be used to define the optimal mesh size for conservation measures to avoid overfishing and achieve sustainable fisheries.

Several authors have reported the high flexibility in the reproductive strategy of the *T. lepturus* at low latitudes and warm regions (e.g., Al-Nahdi *et al.*, 2009). Our results indicate

that *T. lepturus* exhibits an asynchronous ovary development characterized by the presence of oocytes at different stages of development at the same time. The occurrence of mature female, together with GSI data indicates that *T. lepturus* exhibit a prolonged spawning season throughout the year. These findings are consistent with that reported by Khan (2006) showed that *T. lepturus*, off the northwest coast of India, individual fish spawn once in a year but had an extended spawning season (October to May). A year-round spawning cycle indicates that the populations spawn twice a year or are composed of two broodstocks (Al-Nahdi *et al*., 2009; Fakoya and Anetekha, 2019). Additionally, in warmer and less productive environments, smaller batch fecundity, due to smaller size may partly be compensated by longer spawning seasons (Martins and Haimovici, 2000). A prolonged spawning season has also been reported for many other species in temperate waters (Wieland *et al*., 2000). This reproductive strategy has been suggested as reducing the negative impacts of environmental variation on reproductive success (Bobko and Berkeley, 2004).

In conclusion, the results of the current study provide fundamental information on the growth, mortality and reproductive biology of *T. lepturus*, which are prerequisites for effective management of this commercially valuable fishery resource in the Persian Gulf. A detailed study of the reproductive cycle represents the time of the year when the stocks become more vulnerable to fishery's impacts. Given the protracted spawning season, partial closure of the fishery for a portion of the annual spawning season would further increase the abundance of breeding stock, reduce fishing mortality and ensure the long-term sustainability of the fishery. From the results presented in this study, it is possible to determine the minimum size of capture by regulating the mesh size of the nets to better protect the resources. The life-history trait patterns should be further monitored and linked to a stock assessment of the species, to facilitate future interpretation of the impact of increased catch levels on population dynamics and fishery-resource status of the stocks.
